Lecture 4. Higher-order functions

Functional Programming 2017/18

Alejandro Serrano

Goals

- ▶ Define and use higher-order functions
 - Functions which use other functions
 - ▶ In particular, map and foldr
- Use anonymous functions
- Understand function composition

Chapter 7 and 4.5-4.6 from Hutton's book

Usage of map

From the previous lectures...

- map applies a function uniformly over a list
 - ► The function to apply is an *argument* to map

- > map length ["a", "abc", "ab"]
 [1,3,2]
- ▶ It is very similar to a list comprehension
 - > [length s | s <- ["a", "abc", "ab"]]
 [1,3,2]</pre>

Cooking map

1. Define the type

- 2. Enumerate the cases
 - We cannot pattern match on functions

```
map f [] = _
map f (x:xs) = _
```

3. Define the simple (base) cases

```
map f [] = []
```

Cooking map

- 4. Define the other (recursive) cases
 - ▶ The current element needs to be transformed by **f**
 - ► The rest are transformed uniformly by map

```
map f (x:xs) = f x : map f xs
```

It makes **no difference** whether the function we use is global or is an argument

Usage of filter

filter $\,p\,$ xs leaves only the elements in xs which satisfy the predicate $\,p\,$

- ▶ A predicate is a function which returns True or False
- ▶ In other words, p must return Bool

```
> even x = x `mod` 2 == 0
> filter even [1 .. 4]
[2,4]
> largerThan10 x = x > 10
> filter largerThan10 [1 .. 4]
[]
```

Cooking filter

1. Define the type

```
filter :: (a -> Bool) -> [a] -> [a]
```

2. Enumerate the cases

```
filter p [] = _
filter p (x:xs) = _
```

3. Define the simple (base) cases

```
filter p [] = []
```

Cooking filter

- 4. Define the other (recursive) cases
 - ▶ We have to distinguish whether the predicate holds
 - Version 1, using conditionals

Version 2, using guards

```
filter p (x:xs) | p x = x : filter p xs
 | otherwise = filter p xs
```

Alternative definitions using comprehensions

map and filter can be easily defined using comprehensions

map
$$f xs = [f x | x \leftarrow xs]$$

filter $p xs = [x | x \leftarrow xs, p x]$

The recursive definitions are better to reason about code

(Ab)use of local definitions

Suppose we want to double the numbers in a list

▶ We can define a double function and apply it to the list

```
double n = 2 * n
doubleList xs = map double xs
```

This pollutes the code, so we can put it in a where doubleList xs = map double xs where double n = 2 * n

- ▶ But we are still using too much code for such a simple and small function!
 - ► Each call to map or filter may require one of those

Anonymous functions

\ arguments -> code

Haskell allows you to define functions without a name

```
doubleList xs = map (\xspace x -> 2 * x) xs
```

- They are called anonymous functions or (lambda) abstractions
- ▶ The \ symbol resembles a Greek λ

Historical note: the theoretical basis for functional programming is called λ -calculus and was introduced in the 1930s by the American mathematician Alonzo Church

Anonymous functions are just functions

▶ They have a type, which is always a function type

```
> :t \x -> 2 * x 
\x -> 2 * x :: Num a => a -> a
```

You can use it everywhere you need a function

```
> (\x -> 2 * x) 3
6
> filter (\x -> x > 10) [1 .. 20]
[11,12,13,14,15,16,17,18,19,20]
```

Even when you define a function

```
double = \x -> 2 * x
```

Functions which return functions

flip ::
$$(a \rightarrow b \rightarrow c) \rightarrow (b \rightarrow a \rightarrow c)$$

flip f = $y x \rightarrow f x y$

- ► This function is called a **combinator**
 - ▶ It creates a function from another function
- The resulting function may get more arguments
 - They appear in reverse order from the original

> flip map
$$[1,2,3]$$
 (\x -> 2 * x) $[2,4,6]$

Functions are curried

- ▶ In Haskell, functions take one argument at a time
 - The result might be another function

```
map :: (a -> b) -> [a] -> [b]
map :: (a -> b) -> ([a] -> [b])
```

- We say functions in Haskell are curried
- A two-argument function is actually a one-argument function which returns yet another function which takes the next argument and produces a result

Different ways to write

Take a function with three arguments

```
addThree :: Int -> Int -> Int -> Int addThree x y z = x + y + z
```

Parentheses in functions associate to the right

```
addThree :: Int -> (Int -> (Int -> Int))
```

We can define the function in these other ways

Partial application

- Since Haskell functions take one argument at a time, we can provide less than the ones stated in the signature
 - The result is yet another function
 - We say the function has been partially appplied

```
> :t map (\x -> 2 * x)
map (\x -> 2 * x) :: Num b => [b] -> [b]
> :{
    | let doubleList = map (\x -> 2 * x)
    | in doubleList [1,2,3]
    | :}
[2,4,6]
```

Definition by partial application

Instead of writing out all the arguments

doubleList xs = map (
$$\xspace x = x$$
) xs

Haskells make use of partial application if possible

doubleList = map (
$$\xspace x \rightarrow 2 * x$$
)

Note that xs has been dropped from **both** sides

Technical note: this is called η (eta) reduction

Sections

Sections are shorthand for partial application of operators

```
(x \#) = \y -> x \# y -- Application of 1st arg.
(\# y) = \x -> x \# y -- Application of 2nd arg.
```

They help us remove even more clutter

```
doubeList = map (2 *)
largerThan10 = filter (> 10)
```

Warning! Order matters in sections

```
> filter (> 10) [1 .. 20]
[11,12,13,14,15,16,17,18,19,20]
> filter (10 >) [1 .. 20]
[1,2,3,4,5,6,7,8,9]
```

Working with a list of functions

Given a list of numbers, let's create a list of "adders", each of them adding this number to another given one

Working with a list of functions

Let us look at the types of the functions involved

```
(+) :: Int -> (Int -> Int)
-- Generalized type
map :: (a -> b) -> [a] -> [b]
-- In our case a = Int
                a \rightarrow b = Tnt \rightarrow (Tnt \rightarrow Tnt)
         Thus, b = Int \rightarrow Int
map :: (Int -> Int -> Int)
    -> [Int] -> [Int -> Int]
```

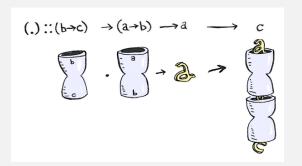

Function composition

Another example of function combinator

ightharpoonup g composed with f, or g after f

(.) ::
$$(b \rightarrow c) \rightarrow (a \rightarrow b) \rightarrow (a \rightarrow c)$$

g . f = $\x \rightarrow g$ (f x)

Examples of function composition

```
not :: Bool -> Bool
even :: Int -> Bool
odd x = not (even x)
odd = not . even -- Better
-- Remove all elements which satisfy the predicate
filterNot :: (a \rightarrow Bool) \rightarrow [a] \rightarrow [a]
filterNot p xs = filter (\xspace x - \xspace x) xs
filterNot p xs = filter (not . p) xs -- Better
filterNot p = filter (not . p) -- Even better
```

Function pipelines

You can define many functions as a pipeline

- Sequence of functions composed one after the other
- ► This style of coding is called *point-free*
 - Even though it actually has more point symbols!

Point-free craziness

You can go even further in this point-free style by using more combinators

Warning! Don't overdo it!

► This definition of average is less readable

Folds

Similar functions

```
sum [] = 0
sum (x:xs) = x + sum xs

product [] = 1
product (x:xs) = x * product xs

and [] = True
and (x:xs) = x && and xs
```

- ▶ The three return a *value* in the [] case
- For the x:xs case, they combine the head with the result for the rest of the list
 - ▶ (+) for sum, (*) for product, (&&) for and

Avoid duplication, abstract!

```
sum [] = 0
sum (x:xs) = x + sum xs
```

Let's replace the moving parts with arguments ${\tt f}$ and ${\tt v}$

► First-class functions are key for abstraction

```
foldr :: (a -> b -> b) -> b -> [a] -> b

foldr _ v [] = v

foldr f v (x:xs) = f x (foldr f v xs)

= x `f` foldr f v xs -- Infix
```

Avoid duplication, abstract!

- ▶ The previous definitions become much shorter
- ▶ The use of foldr conveys an intentions
 - They all compute a result by iteratively applying a function over all the elements in the list

```
sum = foldr (+) 0
product = foldr (*) 1
and = foldr (&&) True
```

foldr is for "fold right"

```
foldr (+) 0 (x : y : z : [])
=
x + foldr (+) 0 (y : z : [])
=
x + (y + foldr (+) 0 (z : []))
=
x + (y + (z + foldr 0 []))
=
x + (y + (z + 0))
```

- ▶ foldr introduces parentheses "to the right"
- ▶ The value is in the innermost part of the list

Another view of foldr

- (:) is replaced by the combination function
- [] is replaced by the initial value

length as a right fold

```
length [] = 0
length (_:xs) = 1 + length xs

foldr _ v [] = v
foldr f v (x:xs) = f x (foldr f v xs)

We want to find f and v such that

length = foldr f v
```

length as a right fold

Case of empty list, []

```
length [] = 0
= v = foldr f v []
```

Case of cons, x:xs

We need to have a function such that

```
f x (length xs) = 1 + length xs
===> f x y = 1 + y
===> f = \xspace \xspace
```

length as a right fold

In conclusion,

```
length = foldr (\_ y -> 1 + y) 0

length [1,2,3]
= -- definition of length
foldr (\_ y -> 1 + y) [1,2,3]
= -- application of foldr
1 + (1 + (1 + 0))
= -- perform addition
3
```

Left folds

foldr (+) 0 [x,y,z]
=
$$(x + (y + (z + 0)))$$

Is it possible to have a "mirror" function fold1?

foldl (+) 0
$$[x,y,z]$$

= $(((0 + x) + y) + z)$

- Parenthesis associate to the left
- Initial value still in the innermost position

Calculating fold1

▶ The case for empty lists is the same as foldr

foldl f v
$$\Pi = v$$

For the general case, notice this fact:

The second argument works as an accumulator

```
foldl f v (x:xs) = foldl f (f v x) xs
```

foldr versus foldl

```
foldr (+) 0 [1, 2, ..., n]
= 1 + foldr (+) 0 [2, ..., n]
= ... = 1 + (2 + ... + (n + 0))
= 1 + (2 + ... + n) = ...

foldl (+) 0 [1, 2, ..., n]
= foldl (+) (0 + 1) [2, ..., n]
= foldl (+) 1 [2, ..., n] -- (!)
= foldl (+) (1 + 2) [..., n]
= foldl (+) 3 [..., n] -- (!)
```

- ▶ With foldr you wait until the end to start combining
- With foldl you compute the value "on the go"
 - fold1 is usually more efficient

foldr versus foldl

In the case of (+), the result is the same

This is not the case for every function

Monoids

One possible set of properties which ensure that the direction of folding does not matter

1. The initial value does not affect the outcome

$$f v x = x = f v x$$
 0 + x = x = x + 0

- ightharpoonup We say that m v is an *identity* for m f
- 2. The way we parenthesize does not affect the outcome

$$f (f x y) z = f x (f y z)$$

 $x + (y + z) = x + (y + z)$

We say that the operation f is associative

A data type with such an operation is called a **monoid**

Avoid explicit recursion

- map, filter, foldr and foldl abstract common recursion patterns over lists
 - Most functions can be written as a combination of those
- Good style: prefer using those functions over recursion
 - ▶ The intention of the code is clearer
 - Less code written means less code to debug
 - Complex recursion suggest that you might be doing too much in one function
 - ► Try to break the function in smaller pieces

Avoid explicit recursion, example

Important concepts

- ► Higher-order functions use or return functions
- ightharpoonup Anonymous functions are introduced by $\x -> \dots$
- ► All functions in Haskell are curried
 - They take one parameter at a time

$$f :: A \rightarrow (B \rightarrow (C \rightarrow D))$$

- Functions can be partially applied
- map, filter, foldr and foldl describe common recursion patterns over lists
